Deciphering phytoplankton community dynamics from HPLC pigment variability

Background
Phytoplankton pigments can provide insight into phytoplankton size classes, functional groups and taxonomy. High Performance Liquid Chromatography (HPLC) pigment analysis has been used worldwide for decades as it remains one of the fastest and easiest ways to characterize community composition. Changes in pigment ratios can be caused by changes in species composition, increased growth of certain groups, or photoacclimation, but this distinction is not always acknowledged.

Objectives
Since HPLC pigment data is often used to calibrate and validate satellite/optical algorithms and models of phytoplankton community composition, our goal was to characterize ranges of pigment variability and evaluate the role of photoacclimation.

Methods
- Compilation of all HPLC data (n=89,000) from 1988-2015 (fig. 1, 2).
- Select surface samples (<20m, n=4,500, fig. 1)
- 8 diagnostic pigments (table 1)
- 2 pigment ratios ~ pico/micro: chlb/fuco and zea/fuco
- Satellite monthly MODIS PAR matchups (fig. 5-11)
- Selected 17 regions (~5x5 degrees, boxes in fig. 1)

Quality control:
1. Level of detection >10^{-4}
2. Ratio of accessory pigments to chl a

Figure 1. Distribution of surface HPLC samples (blue dots) and areas of study in figures 7-9 (red boxes).

Figure 2. Temporal distribution of HPLC samples.

Table 1. Selected pigments and its associated taxonomy and size classification. Adapted from (Vidussi et al., 2000; Peloquin et al., 2013)

Figure 3. Log linear relationship of the sum of all accessory pigments vs. chlorophyll a in HPLC samples.

Results

Figure 4a. Histogram showing latitudinal distribution of samples.

Figure 5. Mean PAR vs. range of PAR variability within 1 degree bins for the location of each HPLC sample, colored by absolute latitude values. PAR units: E m^{-2} day^{-1}

Figure 6. Satellite-derived monthly PAR variability (MODIS 4 km resolution) within each red box in figure 1. Mean, maximum and range of PAR (E m^{-2} day^{-1}) were calculated based on the pixels within each box for each given month.

Regional Variability

Figure 7-9. Relationship between pigment ratios or concentrations and its corresponding monthly mean satellite PAR (E m^{-2} day^{-1}) per region: polar, temperate (Mediterranean) or subtropical. Markers colored by the logarithm of chlorophyll a concentrations (ng/l).

Figure 8. Polar: Palmer

Figure 9. Sub-Tropical: BATS

Figure 10: Relationship between pigment ratios and monthly mean PAR (left panels) or range of PAR variability (right panels). Markers colored by the logarithm of chlorophyll a concentrations (ng/l). PAR (E m^{-2} day^{-1}) calculated from pixels within 1 degree to the location of each HPLC sample.

Figure 11: Relationship between sample latitude and corresponding monthly mean PAR (left panels) or range of PAR variability (right panels) within 1 degree of the location of each HPLC sample. Markers colored by the logarithm of pigment ratios. PAR units: E m^{-2} day^{-1}

Conclusions
- Within regions, the relationship between individual pigment and PAR suggest photoacclimation responses. For pigment ratios, this trend might be driven by community composition and biogeography.
- On a global basis, trends in pigment ratios reproduce expected biogeographical patterns BUT exactly how similar (or different) is the variability in pigment ratios to the variability in phytoplankton size fractions?
